## Abstract

GABA is the main inhibitory neurotransmitter of the central nervous system (CNS) and one of the most abundant neurotransmitters in mammals is distributed in most areas of the brain and participates in 40% of the inhibitory synapses of adult vertebrates. It is produced in the CNS, through the decarboxylation of glutamic acid, catalyzed by glutamic acid decarboxylase (GAD). GABA exerts its inhibitory effect through two types of specific receptors, GABA<sub>A</sub> (ionotropic) and GABA<sub>B</sub> (metabotropic), which show different pharmacological, structural, and molecular differences. Even though GABA plays a key role in the physiology of the CNS modulating different processes, also is involved in some pathologies, furthermore, is a target for several therapeutics drugs. For instance, GABA has important involvement in sleep cycle regulation, and for decades benzodiazepines and gaboxadol have been prescribed for the treatment of insomnia. In epilepsy disease, the pharmacological and gene expression studies suggest a role in the prevention of seizures by blocking the regulation of GABA<sub>A</sub> receptors with specific antagonists. In depression and anxiety, studies indicate changes in the regulation of the genes which encoding GABA receptors. In the same way, GABA receptors have been associated with alcoholism and premenstrual syndrome. In conclusion, experimental evidence suggests, that the same subtype of GABA receptors showed a different pattern of cellular population and subcellular expression in different areas of the brain, modulating the excitability, and neuronal synchronization in different affection pathologies and conditions in humans.

**Key words:** Human. GABA. GABA receptors. Central nervous system. Physiology. Pathophysiology.

## El papel del neurotransmisor GABA en el sistema nervioso central humano, fisiología, y fisiopatología

## Resumen

El GABA es el principal neurotransmisor inhibitorio en el sistema nervioso central (SNC) y uno de los más abundantes en mamíferos; se distribuye en diferentes áreas del cerebro y participa en el 40% de las sinápsis de vertebrados adultos. Su síntesis se realiza en el SNC a través de la descarboxilación del ácido glutámico por acción de la descarboxilasa del ácido glutámico (GAD). El efecto inhibitorio de GABA se ejerce a través de dos tipos de receptores específicos: GABA<sub>A</sub> (ionotrópico)

cos) y GABA<sub>B</sub> (metabotrópicos), los cuales presentan características farmacológicas, estructurales y moleculares diferentes. A pesar de que GABA participa de manera importante regulando diferentes procesos en el SNC, también está involucrado en algunas patologías, por lo que sus receptores son un blanco terapéutico. Por ejemplo, GABA participa en la regulación del ciclo del sueño, y por décadas las benzodiazepinas y el gaboxadol se han prescrito para el tratamiento del insomnio. En epilepsia, estudios farmacológicos y de expresión génica sugieren una participación en la prevención de las crisis al bloquear los receptores GABA<sub>A</sub> con antagonistas específicos. En el caso de la depresión y ansiedad, estudios indican cambios en la regulación de genes que codifican para los receptores a GABA. En este mismo sentido, los receptores a GABA también se han asociado al alcoholismo y al síndrome premenstrual. En conclusión, la evidencia experimental sugiere que el mismo subtipo de receptor a GABA presenta patrones diferentes en las poblaciones celulares y en su expresión subcelular en diferentes áreas del cerebro, modulando la excitabilidad y sincronización neuronal en diferentes condiciones y afecciones patológicas en humanos.

## Introduction

Amino acids (AA) are the basic units of proteins; if there is any AA deficiency, the synthesis of proteins is altered, causing an unbalance in the cellular physiology and organism. AA have different functions and are essential for the physiology of the body; for example, hormones such as insulin, growth hormone, and glucagon, are made up of AAs. It is known that some AAs regulate the *in vitro* and *in vivo* secretion of insulin in pancreatic  $\beta$ -cells. AAs play an important role in different processes related to gene expression, including the modulation of proteins that regulate mRNA<sup>1</sup>.

In the central nervous system (CNS), some AA are neurotransmitters and have a key role in neuronal communication, such as glutamate and glycine. In the case of GABA, despite its chemical structure, it is not considered like AA, because it does not conform proteins. These neurotransmitters are stored in vesicles inside the presynaptic neuron and released into the synaptic cleft by a Ca<sup>2+</sup>-dependent mechanism and in response to a depolarizing stimulus. These neurotransmitters generate excitatory or inhibitory responses through binding to their specific receptors in the post-synaptic neuron or even the same presynaptic cell. A malfunction of these neurotransmitter communication systems is associated with different neurological or psychiatric disorders. For this reason, several pharmacological therapies aim to regulate release mechanisms, receptor binding, or neurotransmitter reuptake.

In this review, we will focus on the inhibitory neurotransmitter GABA ( $\gamma$ -aminobutyric acid), specifically in the participation of their receptors in different neurodegenerative disorders and the different pharmacological strategies aimed at their regulation for the treatment of these pathologies.

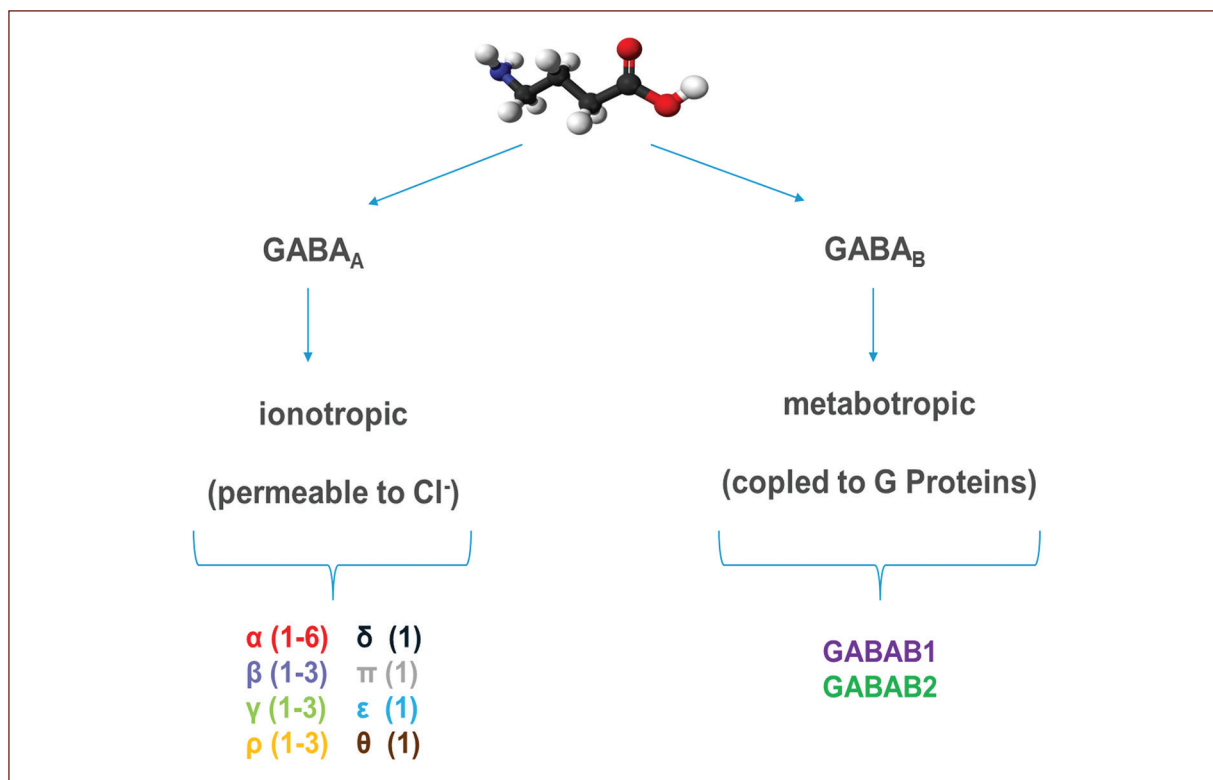

## GABA

GABA is the main inhibitory neurotransmitter of the CNS and one of the most abundant neurotransmitters in mammals. It was first described in the early 1900s, while its presence and participation as a neurotransmitter in the mammalian CNS was determined until the 1950s. During the following two decades, many studies established its mechanism of action, as well as its inhibitory activity in the cerebral cortex<sup>2</sup>. We, currently, know that GABA is distributed in most areas of the brain and participates in 40% of the inhibitory synapses of adult vertebrates.

## GABA metabolism

GABA is produced in the CNS, through the decarboxylation of glutamic acid, and catalyzed by glutamic acid decarboxylase (GAD). In general, the enzymatic activity of GAD is regulated by its expression levels and the degree of association with the cofactor pyridoxal phosphate (PLP)<sup>3</sup>. GAD has two isoforms, GAD<sub>65</sub> and GAD<sub>67</sub>, both encoded by different genes, and different expression patterns, but with similar mechanisms regulating their function<sup>4,5</sup>. GAD<sub>65</sub> is located mainly in the synaptic terminals, where it induces vesicular GABA release in a Ca<sup>2+</sup>-dependent process. GAD<sub>65</sub> dissociates from PLP under physiological conditions and increases its activity depending on the demands of the synaptic release of GABA<sup>6</sup>. Therefore, the main regulatory mechanism for this isoform is the association with its cofactor and not its level of expression<sup>3</sup>.

GAD<sub>67</sub> is expressed in the cytoplasm, it is associated with PLP under physiological conditions, and is regulated by its levels of expression. GAD<sub>67</sub> is involved in cell metabolic activity and is responsible for most of the GABA synthesis in the brain<sup>3</sup>. However, it has been

**Figure 1.** Representative molecular structure of GABA and GABA receptors. GABA is a full agonist of two types of receptors, named according to their mechanism of action. GABA<sub>A</sub> or ionotropic receptors, are protein channels activated by GABA and permeable to Cl<sup>-</sup>. These receptors are conformed by different subunits, six type α, three type β, three type γ, and one each of type δ, ε, π and θ. GABA<sub>B</sub>, or metabotropic receptors, are receptors coupled to G proteins that modulate K<sup>+</sup> and Ca<sup>2+</sup> channels and are conform for only two subunits. The GABA structure was from [https://es.wikipedia.org/wiki/Ácido\\_γ-aminobutírico](https://es.wikipedia.org/wiki/Ácido_γ-aminobutírico) (Last accessed on September 20, 2020).

suggested that cytoplasmic GABA can be released by a Ca<sup>2+</sup>-independent mechanism. If this is correct, then GAD<sub>67</sub> may participate in inhibitory neurotransmission by activating extra-synaptic GABA receptors.

After GABA release into the synaptic cleft, it is re-uptake by the GAT-1 and GAT-3 transporters, these systems are expressed in both neurons and glial cells. GABA catabolism is carried out through the GABA transaminase (GABA-T). GABA-T is dependent on PLP, which, in turn, requires GABA and α-ketoglutarate as substrates, generating glutamic acid, and succinic semialdehyde (SSA) as by-products. SSA can be metabolized into γ-hydroxybutyric acid, which regulates GABA<sub>B</sub> receptors, or can be dehydrogenated to succinate. When GABA is dehydrogenated to succinate via SSA dehydrogenase, it is incorporated into the Krebs cycle, where it participates in cellular energy metabolism. Many clinical and preclinical researches indicate the presence of GABAergic neurons in regions such as

the amygdala, hippocampus, hypothalamus, prefrontal cortex, olfactory bulb, retina, and spinal cord.

## GABA receptors

GABA exerts its inhibitory effect through two types of specific receptors called GABA<sub>A</sub> and GABA<sub>B</sub>, which show different pharmacological, structural, and molecular differences (Fig. 1). GABA<sub>A</sub> receptors, or ionotropic, share its structural and functional properties with the ligand-gated ion channels or “Cys-loop” family, which include glycine (Gly), acetylcholine (ACh), and serotonin (5-HT<sub>3</sub>) receptors<sup>7</sup>. The complexity of GABA<sub>A</sub> receptors lies in the number of subunits they contain, and in the different combinations in which they are assembled. There are also variants generated by splicing or RNA editing<sup>8</sup>. To date, six subunits have been characterized in humans: six type α, three type β, three type γ, and one each of type δ, ε, π, and θ, giving this receptor a high degree of heterogeneity. On the other

**Figure 2.** Structural conformation of GABA<sub>A</sub> receptors. Note the number of subunits that contain, and in the different combinations in which they are assembled. Some of them are variants from splicing, giving this receptor a high degree of heterogeneity. On the other hand, three subunits  $\rho$  have been characterized, which unlike the others form functional homopentamers. In adult mammals, the most abundant receptor conformation, composed of the subunits  $\alpha_1\beta_2\gamma_2$ . However, the number of GABA<sub>A</sub> receptor isoforms expressed in mammals is still unknown.

hand, three subunits  $\rho$  have been characterized, which unlike the others form functional homopentamers with different pharmacological properties. These subunits are considered a subfamily called GABA<sub>C</sub>. In adult mammals, the most abundant isoform is composed of the subunits  $\alpha_1\beta_2\gamma_2$ . However, the number of GABA<sub>A</sub> receptor isoforms expressed in mammals is still unknown<sup>9</sup> (Fig. 2).

GABA<sub>A</sub> receptors are selectively blocked by bicuculline and picrotoxin, and they are allosterically modulated by neurosteroids, barbiturates, and benzodiazepines. At present, there is a continuously increasing large number of regulatory molecules for this type of receptors, due to their pathological importance<sup>10</sup>. In the case of GABA<sub>C</sub> receptors, they are not regulated by modulators and blockers of the GABA<sub>A</sub> receptor. However, they are sensitive to picrotoxin and

1,2,5,6-Tetrahydropyridin-4-yl)methyl phosphonic acid or TPMPA, and specific GABA<sub>C</sub> antagonist<sup>11</sup> (Fig. 3). GABA<sub>A</sub> receptors activation leads to the inhibition of synaptic transmission, due to hyperpolarization in response to a Cl<sup>-</sup> influx through these receptors<sup>12</sup>. Interestingly, during development there is a delay in the expression of Cl<sup>-</sup> mobilization systems, generating a high intracellular concentration of this anion<sup>13</sup>. Therefore, an increase of Cl<sup>-</sup> conductance in response to the activation of GABA<sub>A</sub> receptors generates a Cl<sup>-</sup> outflux current and consequently, cell depolarization, so GABA acts as an excitatory AA during CNS development<sup>14</sup>.

GABA<sub>B</sub> receptors, or metabotropic, belong to the family of G-protein-coupled receptors or GPCRs, which activate slow responses through the second messengers<sup>15</sup>, and have a limited structural diversity, unlike GABA<sub>A</sub> receptors or metabotropic glutamate receptors

**Figure 3.** Pharmacology properties of GABA<sub>A</sub> receptors. At the right is the classical conformation of the GABA<sub>A</sub> receptor, observe the modulation sites were several drugs neuromodulator act to modulate the GABA physiology. These drugs exert their action in different sites of the receptor. Benzodiazepines in the  $\gamma$  subunit; Picrotoxin act in the pore of the channel and blocked; the Barbiturics and neurosteroids in the  $\alpha$  subunit and, Muscimol and Gabazine compete for the GABA binding site located between  $\alpha$  and  $\beta$  subunit. On the left side, are functional homopentameric receptor formed by  $\rho$ . In this case, Picrotoxin, as the  $\alpha_1\beta_2\gamma_2$  conformation, acts in the pore of the receptors, however, TACA and TPMA compete for the GABA binding site.

**Figure 4.** Structural conformation of GABA<sub>B</sub> receptor. This receptor is heterodimers composed of the GABA<sub>B1</sub> or GABA<sub>B1'</sub>, belong to the G-protein-coupled receptors, which activate slow responses through the second messengers, that regulate K<sup>+</sup> and Ca<sup>2+</sup> channels. Nevertheless, despite their poor structural diversity, native GABA<sub>B</sub> receptors show a varied kinetic and pharmacological response.

(mGluRs). GABA<sub>B</sub> receptors are heterodimers composed of the GABA<sub>B1a</sub> or GABA<sub>B1b</sub> subunits combined with the GABA<sub>B2</sub> subunit. Nevertheless, despite their poor structural diversity, native GABA<sub>B</sub> receptors show a varied kinetic and pharmacological response (Fig. 4).

The location of GABA<sub>B</sub> receptors in the synaptic region is key to regulating neurotransmission. Depending on

whether the receptor is presynaptic or postsynaptic, their activation generates an inhibition or disinhibition of synaptic activity. At the post-synaptic level, receptor activation induces a K<sup>+</sup> conductance increase, which is responsible for the “slow” inhibitory events of GABA in the CNS<sup>16</sup>. The activation of this K<sup>+</sup> conductance, coupled with negative regulation of Ca<sup>2+</sup> influx at the presynaptic

**Figure 5.** GABA pathways in the brain. The GABAergic system goes throughout the amygdala, hippocampus, hypothalamus, prefrontal cortex, olfactory bulb, including the spinal cord and even the retina. This wide expression of the GABAergic cells indicates the key role of this inhibitory neurotransmitter in functions in the CNS, such as behavior, motor control, mood, sleep, among others. Modified from Brain Chat. [https:// thebrainchat.com/photos/gamma-aminobutyric-acid-gaba-is-a-naturally-occurring-amino-acid-that-works-as-a/1243388282530289/](https://thebrainchat.com/photos/gamma-aminobutyric-acid-gaba-is-a-naturally-occurring-amino-acid-that-works-as-a/1243388282530289/).

level, decreases the release of GABA by regulating the inhibitory effect mediated by this neurotransmitter<sup>17</sup>.

## GABA and the CNS

The proper functioning of the CNS depends on the balance between the excitatory and inhibitory neurotransmitter systems. The excitatory system is regulated by glutamate, while the inhibitor system is regulated by GABA through interneurons, which modulate the excitatory level generated by glutamate release. These interneurons control the flow of information and the synchronization of the cerebral cortex, despite the existence of a 1:5 proportion with glutamatergic neurons. Suggesting, that the numerical balance between neurons and interneurons determines brain functionality, in the case of the cerebral cortex, the proportion 1:5 indicates that this region is mainly excitatory.

Studies in animal models indicate the presence of GABAergic neurons in regions such as the amygdala,

hippocampus, hypothalamus, prefrontal cortex, olfactory bulb, retina, and spinal cord, this observation was corroborated also in human studies. This wide expression of the GABAergic cells indicates that this inhibitory neurotransmitter is involved in many functions in the CNS (Fig. 5), for instance, the thalamocortical pathway, which regulates primordial functions such as behavior, motor control, mood, sleep, and among others.

The thalamocortical pathway consists of GABAergic neurons that project from the thalamic reticular nucleus (nRT) toward the ventral basalis (VB), generating an inhibitory "loop" for a self-modulation of the nRT. GABAergic neurons of the nRT receive the glutamatergic stimulation from the VB and the cortico-thalamic fibers that are projected from the layer six of the cerebral cortex. In this "loop context," GABA<sub>A</sub> receptors are in glutamatergic thalamocortical and cortico-thalamic neurons, as well as in the GABAergic neurons themselves<sup>18</sup>.

Thanks to benzodiazepines it has been understood the functional differences between the GABA<sub>A</sub>

receptors located in the nRT and the thalamic relay neurons. Since benzodiazepines increase the neurotransmission regulated by GABA<sub>A</sub> receptors, these compounds exacerbate absence seizures; however, they show some therapeutic efficacy in clinical and animal models. This double function of benzodiazepines is because they increase the inhibition regulated by GABA<sub>A</sub> receptors in the nRT, causing a decrease in the inhibitory stimulus of the nRT toward the thalamic relay neurons<sup>19</sup>. Experimental evidence indicates the participation of GABA<sub>B</sub> receptors in the pathogenesis of absence seizures<sup>20</sup>. GABA<sub>B</sub> receptors regulate K<sup>+</sup>, activating low-threshold Ca<sup>2+</sup> potentials and consequently, burst firing, and the oscillatory behavior of thalamic neurons. Agonists of these receptors exacerbate absence seizures in animal models in a greater proportion than GABA<sub>A</sub> receptors.

## **Disorders associated with GABA receptors**

### **Sleep disorders**

GABA has important involvement in sleep cycle regulation, and for decades benzodiazepines and gaboxadol (alternative to benzodiazepines) have been prescribed for the treatment of insomnia with certain tolerance; however, these compounds have side effects such as addiction, hallucinations, and disorientation. Several alterations in the thalamocortical pathway are associated with sleep problems, a common symptom in different neurological pathologies, and where it has been described an increase in GABA levels and an altered function of GABAergic receptors that contain the  $\delta$  subunit ( $\delta$ -GABA<sub>A</sub>)<sup>21</sup>.

### **Epilepsy**

It is known that the mechanisms regulated by the GABA<sub>A</sub> receptor participate in the partial or generalized generation of tonic-clonic seizures. Pharmacological and gene expression studies suggest a role in the prevention of seizures by blocking the regulation of GABA<sub>A</sub> receptors with specific antagonists. Studies point to changes or differences in the expression of subunits of GABA<sub>A</sub> receptors that correlate with epileptogenesis<sup>22</sup>. There is a relationship between mutations in the  $\gamma$ 2 subunit and epilepsy in humans<sup>23</sup>, similarly, mutations in the gene encoding the  $\delta$  subunit have been associated with some forms of congenital epilepsy in humans<sup>24</sup>.

The regulation system through the GABA<sub>B</sub> receptor participates in the prevention of tonic seizures. In humans, an upregulation of the mRNA of the GABA<sub>B</sub> R1 subunit in the CA1 region, dentate gyrus, and hilus region of the hippocampus has been determined in samples of patients with temporal lobe epilepsy<sup>25</sup>. A report indicates an increase in antagonist sites per neuron in the CA3 and the hilus regions of the hippocampus in patients with temporal lobe epilepsy<sup>26</sup>. On the other hand, it was determined that a GABA<sub>B</sub> R1 polymorphism (G1465A) confers a high susceptibility to temporal lobe epilepsy and increases the severity of the condition<sup>27</sup>. GABA<sub>B</sub> R1 knockout mice show several seizures per day, as well as depression-like behavior<sup>28</sup>.

### **Anxiety disorders**

GABA receptors are of great interest for the treatment of anxiety disorders, due to the therapeutic use of benzodiazepines for these conditions. Tests with positron emission tomography and single-photon emission tomography in patients with panic attacks showed an alteration in benzodiazepine binding sites in different areas of the brain<sup>29</sup>. Family studies indicate an association between inhibition of behavior and anxiety disorders. Smoller et al. found an association between an intronic polymorphism in the GAD65 gene with anxiety disorders<sup>30</sup>.

### **Schizophrenia**

There are numerous hypotheses about the pathophysiology of schizophrenia, one of which proposes an alteration of GABA-regulated neurotransmission<sup>31</sup>. Changes in the expression of genes related to the different subunits that form GABA receptors have been observed<sup>32</sup>. However, this is not specific for GABA, since there are also changes in gene expression of other neurotransmitters. Another evidence that supports the GABA hypothesis in schizophrenia is that the treatment of this pathology with antiepileptic drugs shows positive clinical results in schizophrenic patients<sup>33,34</sup>. The use of benzodiazepines in combination with antiepileptic drugs reduces considerably the symptoms of schizophrenia and anxiety. On the other hand, the administration of valproate with neuroleptics controls efficiently irritability symptoms and violent behaviors.

The genes that encode GABA<sub>B</sub> R1 are located within the loci of schizophrenia, suggesting the participation of this receptor in this disorder<sup>35</sup>. These observations suggest that the GABA<sub>B</sub> R1 receptor may be a pharmacological target for schizophrenia.

## Depression

In recent years, different reports showed evidence about the association between GABA and depression. For example, a decrease of this neurotransmitter in the cerebrospinal fluid of patients with depression has been reported<sup>36</sup>. Magnetic resonance spectroscopy in depressive patients showed a reduction in GABA levels, mainly in the occipital cortex (OCC) and in some areas of the prefrontal cortex (PFC)<sup>37</sup>. Studies indicate changes in the regulation of the genes which encoding GABA receptors. For example, Choudary and col. showed the deregulation of the  $\beta_3$ ,  $\gamma_2$ , and  $\delta$  subunits in the frontal cortex<sup>38</sup>. In this regard, the postmortem analysis by PCR of different brain regions from suicide victims with depression showed alterations in the  $\alpha_5$ ,  $\gamma_1$ , and  $\gamma_2$  subunits of the dorsolateral and lateral inferior PFC<sup>39</sup>. Fatemi and col. found an increase in the  $\alpha_2$ ,  $\alpha_2$ ,  $\gamma_3$ , and  $\epsilon$  subunits in the cerebellum of non-suicidal patients with depression<sup>40</sup>.

## Premenstrual dysphoric disorder (PMDD)

Changes in cognition, mood, and sensitivity to medications throughout the premenstrual cycle have been attributed to hormonal regulation of GABAergic transmission<sup>41</sup>. PMDD occurs during the luteal phase of the menstrual cycle and is characterized by significant alterations in behavior, mood, and a physical limitation that compromises personal, social, and professional development. In healthy women, plasmatic levels of GABA increase from the follicular to the luteal phase, while they decrease in women suffering from PMDD<sup>42</sup>. However, in the CNS, GABA levels increase in this same phases<sup>43</sup>. An increase in cortical inhibitory activity has been reported in healthy women, whereas this effect is not observed in women with PMDD<sup>44</sup>. Deregulation of GABA levels possibly is secondary to the action of allopregnanolone, a metabolite of progesterone secreted during the luteal phase. This hormone acts on GABA<sub>A</sub> receptors that contain the  $\alpha_4$  and  $\delta$  subunits<sup>45</sup>. During periods of fluctuation of progesterone concentrations, there are changes in the expression of the  $\alpha_4$  and  $\delta$  subunits in the CA1 region of the hippocampus. Furthermore, a decrease in the  $\alpha_1$  subunit has been observed<sup>42</sup>.

## Alcoholism

It is well known that the main ethanol target in the CNS is the GABA<sub>A</sub> receptors<sup>46</sup>, for example, studies in

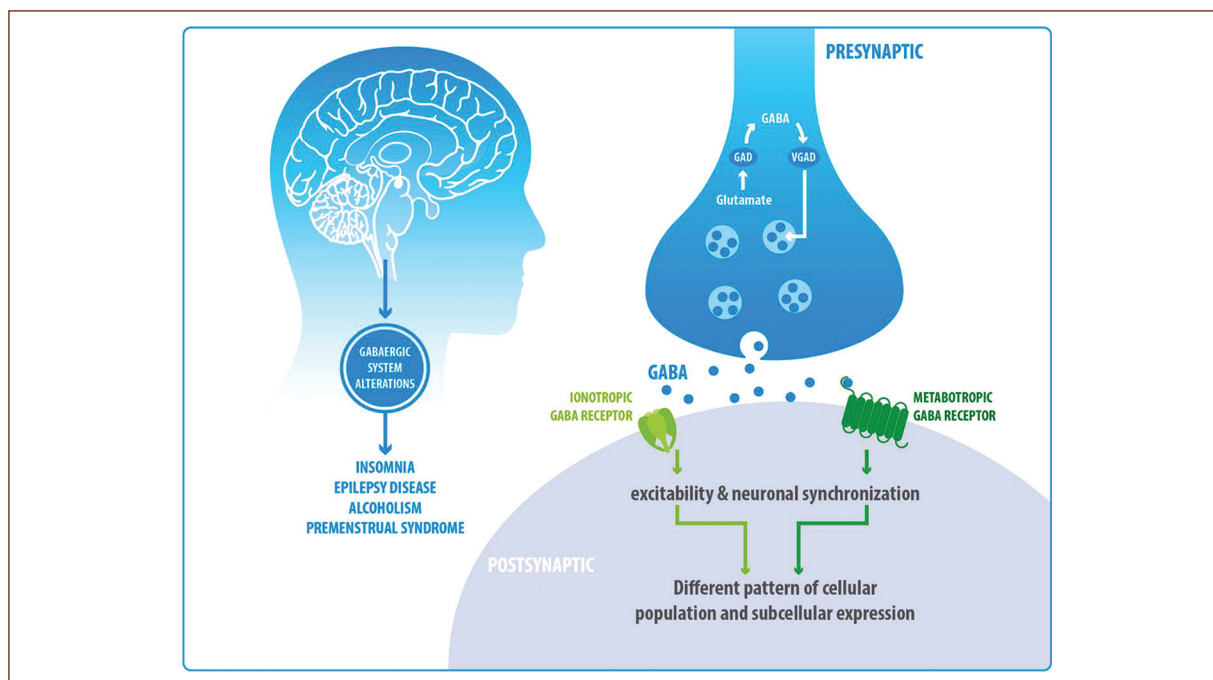

rodents show that the systemic administration of GABA receptors agonists or antagonists modulates the ethanol consumption<sup>47</sup>. GABA<sub>A</sub> receptors increase their probability of aperture and/or their affinity for the agonist after an acute ethanol intake. They are generally potentiated by low concentrations of ethanol (5-50 mM) that correspond to very low intake in humans (a couple of drinks). Chronic exposure to ethanol generates different specific neuroadaptations in GABAergic synapses in different regions of the brain. Furthermore, chronic exposure to ethanol alters the expression of different subunits of GABA<sub>A</sub> receptors at the transcriptional level in different regions of the brain involved in the development of alcohol dependence. For example, in the cerebral cortex, chronic exposure to ethanol decreases mRNA and the expression of  $\alpha_1$ ,  $\alpha_2$ , and  $\alpha_3$  subunits, and increases the expression of  $\alpha_4$ ,  $\beta_1$ ,  $\beta_2$ ,  $\beta_3$ ,  $\gamma_1$ , and  $\gamma_2$  subunits<sup>48</sup>. In humans, sequencing assays have identified different genes encoding GABA<sub>A</sub> receptors associated with alcohol consumption, such as  $\alpha_3$  (GABRA3) in the prefrontal cortex,  $\gamma_1$  (GABRG1), and  $\gamma_2$  (GABRG2) in the hippocampus<sup>49</sup>. These expression changes probably alter the assembly of GABA<sub>A</sub> receptors, modifying their binding affinity to the ligand and, consequently, their function. In the case of the hippocampus, alterations in the expression of GABA<sub>A</sub> receptors depend on the time of exposure to ethanol. A 40-day chronic exposure significantly increased the levels of the  $\alpha_4$  subunit; however, no alterations were observed in the  $\alpha_1$ ,  $\alpha_2$ ,  $\alpha_3$ ,  $\beta$  (2/3), or  $\gamma_2$  subunits<sup>50</sup>. These results indicate a regulation in the expression of subunits of GABA<sub>A</sub> receptors specific to each region of the brain that is dependent on the length of exposure to ethanol.

In the case of GABA<sub>B</sub> receptors, they are determinants of the specificity of ethanol effects on certain regions of the brain. For example, Peris and col. showed that chronic ethanol treatment increases the release of GABA, decreasing long-term potentiation<sup>51</sup>. Exposure to baclofen (GABA<sub>B</sub> antagonist) decreases this release of GABA, whereas 2-OH-saclofen (GABA<sub>B</sub> antagonist) enhances it. This chronic effect of ethanol on the release of GABA into the synaptic cleft could explain the reduction in long-term potentiation observed after chronic exposure to ethanol.

## Conclusion

Its complex structural diversity, associated with its differential expression pattern in the neural loops of the brain, makes it very difficult to understand its inhibitory

**Figure 6.** Its complex structural diversity, associated with its differential expression pattern in the neural loops of the brain, makes it very difficult to understand its inhibitory control in different neural networks. Although our knowledge about the specific functions of GABAergic receptors in a neural loop is limited, there is evidence that suggests that the same subtype of GABAergic receptors can be expressed in different neuronal populations with different subcellular locations and in different areas of the brain, modulating the excitability and neuronal synchronization in different ways (Fig. 6). Therefore, understanding the role that GABA plays in the brain is possible only through the specific study of a receptor subtype, a loop, or a neuronal type, considering important variables such as previous synaptic physiology, synaptic activity, sex, or the circadian cycle, are partially explored along with GABA.

control in different neural networks. Although our knowledge about the specific functions of GABAergic receptors in a neural loop is limited, there is evidence that suggests that the same subtype of GABAergic receptors can be expressed in different neuronal populations with different subcellular locations and in different areas of the brain, modulating the excitability and neuronal synchronization in different ways (Fig. 6). Therefore, understanding the role that GABA plays in the brain is possible only through the specific study of a receptor subtype, considering important variables such as synaptic activity, sex, or the circadian cycle, are partially explored along with GABA.
